### Abstract

Embedded control applications such as drive-by-wire in cars require dependable interaction between various sensors, processors, and actuators. This paper addresses the design of low-cost communication networks guaranteeing to meet both the performance and fault-tolerance requirements of such distributed applications. We develop a fault-tolerant allocation and scheduling method, which maps messages onto a low-cost multiple-bus system to ensure predictable inter-processor communication. The proposed method targets time-division multiple access (TDMA) communication protocols, and is applicable to protocols such as FlexRay and TTP which have recently emerged as possible networking standards for embedded systems such as automobile controllers. Finally, we present a case study involving some advanced automotive control applications to show that our approach uses the available network bandwidth efficiently to guarantee message deadlines.

# 1. Introduction

Embedded computer systems are being increasingly used in cost-sensitive consumer products such as automobiles to replace safety-critical mechanical and hydraulic systems. Drive-by-wire is one example where traditional hydraulic steering and braking are replaced by a networked microprocessor-controlled electro-mechanical system [1]. Sensors measure the steering-wheel angle and brake-pedal position, and processors calculate the desired road-wheel and braking parameters, which are then applied via electromechanical actuators at the wheels. Other computerized vehicle-control applications including adaptive cruise control, collision avoidance, and autonomous driving are also being developed [2]. These applications will be realized as real-time distributed systems requiring dependable interaction between sensors, processors, and actuators. This paper addresses the design of low-cost communication

networks to meet both the performance and fault-tolerance requirements of such applications.

Related work in communication synthesis for distributed embedded systems belongs to two broad categories—those that assume a fixed network topology and schedule messages to meet their deadlines [3–5], and those that synthesize a topology satisfying message deadlines [6,8].

The authors of [3] assume a fixed network topology and using the controller area network (CAN) protocol, schedule messages by assigning appropriate priorities to help meet their deadlines. Off-line algorithms to schedule both tasks and messages in combined fashion while minimizing overall schedule length are developed in [4,5]. In [7], processors are assigned priorities for network access and the corresponding messages are transmitted using a fixedpriority scheduling scheme.

A network topology satisfying message deadlines can also be constructed from application requirements. Modeling embedded applications as task graphs, [6] estimates the communication delay for inter-processor messages and schedules them on the minimum number of buses using the CAN protocol, while [8] generates point-to-point communication links for messages.

Unlike [3–5,7] which assume a given topology, the approach proposed in this paper synthesizes a fault-tolerant network topology from application requirements. While synthesis methods such as [6] assume an underlying CAN communication protocol and arbitrate bus access using message (processor) priorities, we target time-division multiple access (TDMA) communication protocols where processors are allotted transmission slots according to a static, periodic, and global communication schedule [9]. Also, TDMA protocols such as TTP [10] and FlexRay [11] have recently emerged as possible networking standards for an important class of embedded systems-automobiles.

Rather than generate arbitrary networks, we restrict the topology space to multiple-bus systems. Fig. 1 shows an example where each processor  $P_i$  connects to a subset of the communication buses. A co-processor handles message communication independently without interfering with task execution on  $P_i$ . A multiple-bus topology allows fault-tolerant message allocation. Also, since communication protocols for the embedded systems of interest are typically implemented over low-cost physical media, individual buses have limited bandwidth; multiple buses may be needed to accommodate the message load.

Given a set of distributed applications modeled as task graphs  $\{G_i\}$ , our approach constructs a low-cost communication network satisfying both the performance and faulttolerance requirements of each  $G_i$ . Messages are allocated and scheduled on the minimum number of buses  $\{B_j\}$  where each  $B_j$  has a specified bandwidth. We now summarize the major features of our approach:

- It assumes a multi-rate system where each graph G<sub>i</sub> may have a different execution period, period(G<sub>i</sub>).
- It targets a generic TDMA communication protocol.
- It supports dependable message communication by establishing redundant transmission paths between processors, thereby tolerating a bounded number of permanent bus failures.
- It uses network bandwidth efficiently by reusing transmission slots allotted to a processor between the multiple messages sent by it.

Finally, using some representative automotive control applications, we show that the proposed method guarantees predictable message transmission while reducing bandwidth utilization.

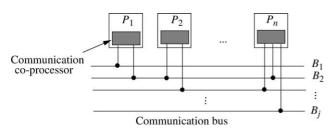

Fig. 1. An example multi-bus system where each processor connects to a subset of the communication buses.

The rest of this paper is organized as follows. Section 2 presents an overview of the proposed approach, while Section 3 discusses some preliminaries. The message allocation method is developed in Section 4 and Section 5 presents the case study. We briefly discuss some related issues and conclude the paper in Section 6.

# 2. Design overview

As the primary objective, we construct a network topology meeting the fault-tolerance and performance goals of the embedded applications. The secondary objective is to minimize hardware cost in terms of communication buses. An iterative method is developed where a feasible network topology satisfying performance goals is first obtained. Its cost is then reduced via a series of steps, which minimize the number of buses by appropriately grouping (clustering) messages while preserving the feasibility of the original solution. Since clustering is NP-complete [12], we use heuristics to obtain a feasible solution.

Fig. 2 shows the main steps of the proposed heuristic approach. For a given allocation of tasks to processors, FT-DESIGN accepts the set of task graphs and processors  $\{P_i\}$  as inputs, and returns as output, a low-cost network topology comprising identical buses  $\{B_j\}$ . Redundant routes are provided for messages with specific fault-tolerance requirements; for a *k*-fault-tolerant (*k*-FT) message  $m_i$ , *k* replicas or copies are allocated to separate buses. The network is synthesized assuming a generic TDMA protocol, and can accommodate specific cases such as TTP [10] and FlexRay [11] after some modifications.

We assume that each task graph  $G_i$  must meet its deadline by the end of its period, period( $G_i$ ). First, the graph deadline is distributed over its tasks to generate a scheduling range [ $r_i$ ,  $d_i$ ] for each task  $T_i$  where  $r_i$  and  $d_i$  denote its release time and deadline, respectively. The initial network topology is obtained by simply allocating each interprocessor message  $m_i$  to a separate bus. Without bus contention,  $m_i$ 's transmission delay is given by the message size and bus bandwidth, and the overall solution is feasible if all tasks complete before their respective deadlines. Section 3 discusses these initial steps in greater detail.

The number of communication buses in the initial solution is then minimized via an iterative message clustering procedure which groups multiple messages on bus  $B_j$ . A message  $m_i$  is grouped with an existing cluster  $C_j$  if the resulting allocation satisfies the following requirements:

- No two replicas of a k-FT message are allocated to  $C_i$ .
- All messages belonging to  $C_j$  continue to meet their deadlines.
- The duration (length) of the communication schedule corresponding to C<sub>j</sub> does not exceed a designer-specified threshold; if a dedicated co-processor handles message

F	<b>Procedure FT-DESIGN</b> ( $\{G_i\}, \{P_i\}$ ) /* $\{G_i\}$ := Task graphs, $\{P_i\}$ := Processors */
	for (each $G_i$ )
	Distribute $G_i$ 's deadline to obtain the scheduling range $[r_i, d_i]$ for each task $T_i$ ;
	for (each k-FT message $m_i$ ) begin /* Obtain the initial network topology */
	Determine $m_i$ 's transmission delay $tdelay(m_i)$ ;
	Allocate each copy of $m_i$ to a separate bus $B_i$ ;

	for (each task $T_i$ ) begin /* Determine task schedulability */
	$w_i :=$ Worst-case response time of $T_i$ on its allocated processor $P_i$ ;
	<b>if</b> $(w_i + tdelay(m_i) > d_i - r_i)$ <b>return</b> $\emptyset$ ; /* Solution is infeasible */
	end;
	$s_{\text{clust}} := $ <b>SYNTH</b> ({ $m_i$ }); /* Synthesize low-cost topology */
	Allocate each cluster $C_j$ in $s_{clust}$ to a separate bus $B_j$ ;
	<b>return</b> $\{B_j\}$ ; /* Return the set of communication buses */

Fig. 2. The overall approach to fault-tolerant communication network synthesis.

communication as in Fig. 1, the schedule must be compact enough to fit within the available memory.

The proposed clustering approach also uses bus bandwidth efficiently by sharing or re-using transmission slots between multiple messages sent by a processor whenever possible. Each message cluster is allocated to a separate bus in the final topology. Section 4 describes the clustering procedure in greater detail.

# 3. Preliminaries

This section shows how to obtain the initial solution where tasks are assigned deadlines and scheduled on processors, and messages allocated to separate communication buses.

# 3.1. Deadline assignment

Initially, only the entry and exit tasks having no predecessors and successors, respectively, have their release times and deadlines fixed. To schedule an intermediate task  $T_i$  in the task graph, however, its scheduling range  $[r_i, d_i]$  must first be obtained. This is termed the *deadline* assignment problem where the deadline  $D_i$  of the task graph  $G_i$  must be distributed over each intermediate task

such that all tasks are feasibly scheduled on their respective processors. Deadline distribution is NP-complete and various heuristics have been proposed to solve it. We use the approach of Natale and Stankovic [14] which maximizes the slack added to each task in graph  $G_i$  while still satisfying its deadline  $D_i$ . Their heuristic is simple, and for general task graphs, its performance compares favorably with other heuristics [13].

We now describe the deadline distribution algorithm. Entry and exit tasks in the graph are first assigned release times and deadlines. A path, path<sub>i</sub> through  $G_i$  comprises one or more tasks  $\{T_i\}$ ; the slack available for distribution to these tasks is slack<sub>i</sub> =  $D_i - \sum c_i$  where  $D_i$  is the deadline of path<sub>i</sub> and  $c_i$  the execution time of a task  $T_i$  along this path. The distribution heuristic in [14] maximizes the minimum slack added to each  $T_i$  along path, by dividing slack, equally among tasks. During each iteration through  $G_i$ , path<sub>i</sub> minimizing  $slack_i/n$ , where *n* denotes the number of tasks along path<sub>i</sub>, is chosen and the corresponding slack added to each task along that path. The deadlines (release times) of the predecessors (successors) of tasks belonging to path, are updated. Tasks along path, are then removed from the original graph, and the above process is repeated until all tasks are assigned release times and deadlines.

We use the graph in Fig. 3(a) to illustrate the above procedure. First, the release time of entry task  $T_1$ 

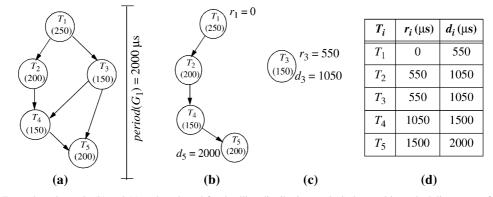

Fig. 3. (a) Example task graph, (b) and (c) paths selected for deadline distribution, and (d) the resulting scheduling ranges for each task.

and the deadline of exit task  $T_5$  are set to  $r_1=0$  µs and  $d_5=2000$  µs, respectively. Next, we select the path  $T_1T_2T_4T_5$  shown in Fig. 3(b); the total execution time of tasks along this path is 800 µs, and as per the heuristic, a slack of (2000-800)/4=300 µs is distributed to each task. Once their release times and deadlines are fixed, these tasks are removed from the graph. Fig. 3(c) shows the remaining path comprising task  $T_3$  which has its release time and deadline fixed by  $T_1$  and  $T_4$ , respectively. Fig. 3(d) shows the resulting scheduling range for each task.

#### 3.2. Task scheduling

Once the scheduling ranges of tasks in the graph are fixed, each  $T_i$  may now be considered independent with release time  $r_i$  and deadline  $d_i$ , and scheduled as such. To tackle multi-rate systems, we use *fixed-priority scheduling* where tasks are first assigned priorities according to their periods [15], and at any time instant, the processor executes the highest-priority ready task. Again, the schedule is feasible if all tasks finish before their deadlines; feasibility analysis of schedules using simple closed-form processor-utilizationbased tests has been extensively studied under fixed-priority scheduling [15]. However, in addition to feasibility, we also require task  $T_i$ 's response time  $w_i$ , given by the time interval between  $T_i$ 's release and finish times; the response time is used in the next stage of our algorithm to determine the message delays to be satisfied by the network.

For multi-rate task graphs, the schedules on individual processors are simulated for a duration equal to the least common multiple (LCM) of the graph periods [16]. Since this duration evaluates all possible interactions between tasks belonging to the different graph iterations, the worst-case response time for each task  $T_i$  is obtained. Fig. 4(a) shows a simple multi-rate system comprising two task graphs with periods 2000 and 3000 µs; Fig. 4(b) and (c) show the task allocation and scheduling ranges, respectively. Fig. 4(d) shows the corresponding schedule for 6000 µs—the LCM of the graph periods. Task response times within this time interval are shown in Fig. 4(e). Multiple iterations of a task are evaluated to obtain its worst-case response time. For example, in Fig. 4(e), the first iteration of tasks  $T_1$ ,  $T_2$ , and  $T_4$ (in bold) has the maximum response time among the iterations within the given time duration. The task scheduling on processors is successful if, for each task  $T_i$ ,  $w_i \le d_i - r_i$ . However, for the overall solution to be feasible, all messages must also meet their deadlines.

#### 3.3. Initial network topology

A *k*-FT message  $m_i$  sent by task  $T_i$  has deadline delay  $(m_i) = d_i - r_i - w_i$  where  $w_i$  denotes  $T_i$ 's worst-case response time. Initially, the network topology allocates a separate communication bus for each message copy. Therefore, in this topology,  $m_i$  experiences no network contention and its transmission delay is size $(m_i)/B_j^{\text{speed}}$  where size $(m_i)$  and  $B_j^{\text{speed}}$  denote the message size in bits and bus bandwidth in KB/s, respectively. The solution is feasible if, for each  $m_i$ , delay $(m_i)$  is greater than the corresponding transmission delay.

#### 4. Fault-tolerant message clustering

We now develop a clustering approach to reduce the cost of the initial network topology obtained in Section 3 where

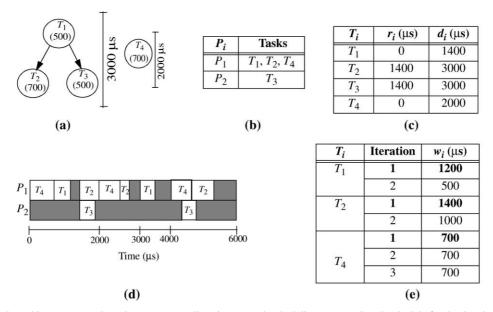

Fig. 4. (a) An example multi-rate system, (b) task-to-processor allocation, (c) task scheduling ranges, (d) task schedule for the duration of the least common multiple of the task periods, and (e) the response times of different task iterations over the simulated time interval.

Fig. 5. A TDMA-based allocation of transmission slots to processors on communication bus  $B_{j}$ .

multiple messages are grouped on a single bus while preserving the feasibility of the original solution. The fault-tolerance requirement of each k-FT message is also satisfied during this procedure.

First, we briefly review message transmission in a typical TDMA communication protocol. As an example, we choose the FlexRay protocol currently under development by a consortium of automotive companies to provide predictable communication for distributed control applications [11]. Fig. 5 shows the TDMA scheme where messages are transmitted according to a static, periodic, and global communication schedule called a *round* comprising identical-sized slots. Each processor  $P_j$  is allotted one or more sending slots during a round where both slot size and the number of slots per round are fixed by the system designer. Though successive rounds are constructed identically, the messages sent by processors may vary during a given round.

We now state the fault-tolerant message clustering problem as follows. Given a communication deadline delay( $m_i$ ) for each k-FT message  $m_i$  sent by processor  $P_j$ , construct TDMA rounds on the minimum number of communication buses such that during any time interval corresponding to delay( $m_i$ ),  $P_j$  is allotted a sufficient number of transmission slots to transmit  $m_i$ . Allocation of messages to multiple buses is related to *bin-packing* where fixed-size objects (messages) are packed into a bin (round) of finite size while minimizing the number of bins. The general binpacking problem is NP-complete and heuristics are typically used to obtain a solution [17].

We treat each  $m_i$  as a periodic message with period, period $(m_i)$  equal to its deadline delay $(m_i)$  and generate message clusters  $\{C_j\}$ , such that the corresponding TDMA round, round $(C_j)$  satisfies the constraints previously introduced in Section 2:

- No two replicas of a k-FT message m<sub>i</sub> are allocated to C<sub>j</sub>.
- The duration of round(*C<sub>j</sub>*) does not exceed a designer-specified threshold.
- The slots within round(*C<sub>j</sub>*) guarantee *m<sub>i</sub>*'s deadline, i.e. the time interval between successive sending slots for *m<sub>i</sub>* equals its period.

Each message cluster  $C_j$  is allocated to a separate communication bus in the final network topology. Our method also makes efficient use of bus bandwidth by minimizing the number of transmission slots needed to satisfy message deadlines within a TDMA round by reusing slots between messages sent by a processor whenever possible.

We assume an upper bound on TDMA-round duration provided by the designer in terms of the maximum number

of transmission slots  $n_{\text{max}}$  and slot duration  $\Delta_{\text{slot}}$ . Typically, the choice of  $n_{\text{max}}$  depends on the memory limitations of the communication co-processor such as the number of transmit and receive buffers. Each transmission slot within a round has duration  $\Delta_{\text{slot}} = \min_i \{\text{size}(m_i)\}/B_j^{\text{speed}} \ \mu$ s. The message period delay $(m_i)$ , originally expressed in microseconds, is now discretized as  $\lfloor \text{delay}(m_i)/\Delta_{\text{slot}} \rfloor$  and expressed in terms of transmission-slot intervals. To simplify the notation, we will use delay $(m_i)$  to denote this discrete quantity from here on.

To guarantee message  $m_i$ 's deadline, the corresponding slot allocation must satisfy both its periodicity requirement and a distance constraint between successive  $m_i$  transmissions as the following example illustrates. Fig. 6(a) shows an allocation scenario for message  $m_1$  having delay $(m_1) = 2$  slots within a TDMA round of duration four slots where  $m_1$  requires one slot for transmission. Though  $m_1$ 's periodicity requirement may be satisfied by simply allocating sufficient slots within each of its periods, it results in missed deadlines. The interval between successive  $m_1$ transmissions may be as close to one and as far as three slots away. As Fig. 6(a) shows, in the worst case,  $m_1$  may be allocated a transmission slot just before the end of its current period and one immediately at the start of its next period. Clearly, this results in a deadline violation. Similar problems may also occur when multiple messages are clustered. Fig. 6(b) shows TDMA rounds corresponding to messages  $m_1$  and  $m_2$  with periods  $period(m_1)=2$  and  $period(m_2) = 5$  slots, respectively. Transmission slots are allocated in first-fit (FF) fashion where messages are ordered in terms of increasing period and the first available slots allocated to each  $m_i$  within the round. The slot allocation in Fig. 6(b) results in a deadline violation where the minimum and maximum distances between successive slots for  $m_2$  are 4 and 6 slots, respectively. Therefore, to guarantee message  $m_i$ 's deadline, the corresponding allocation must satisfy a maximum distance between successive  $m_i$  transmission slots equal to  $period(m_i)$ . Note that in the above example, message deadlines may be satisfied by modifying their periods appropriately. Fig. 6(c) shows the slot allocation for both messages after  $m_2$ 's period is modified to four slots. It is easily checked that the distance constraint of two and four slots for successive transmissions of  $m_1$  and  $m_2$ , respectively, is satisfied.

The above discussion suggests that the original message periods may need modification prior to allocating slots within the TDMA round. We adopt a strategy where the periods of all messages within a cluster are constrained to be harmonic multiples of some base period  $p_{\text{base}}$ , i.e. period $(m_i) = 2^k p_{\text{base}}$ . A similar concept is used while scheduling tasks in real-time systems requiring a specific temporal separation between successive task executions [18,19]. We constrain each  $m_i$ 's period to be the maximum integer period $(m_i) \le n_{\text{max}}$  satisfying  $2^k p_{\text{base}} \le \text{delay}(m_i) < 2^{k+1} p_{\text{base}}$ ; if  $p_{\min} = \min_i \{\text{period}(m_i)\}$  is the smallest period among the messages, then  $p_{\min}/2 < p_{\text{base}} \le p_{\min}$ .

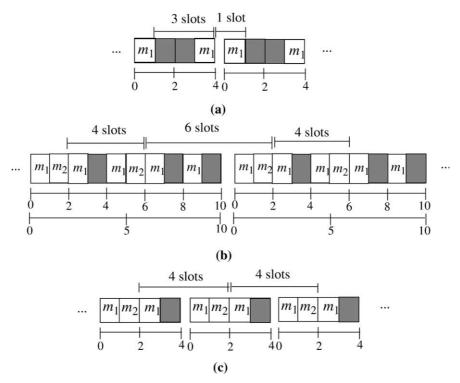

Fig. 6. (a) Message allocation resulting in a missed deadline, (b) a clustering of multiple messages resulting in missed deadlines, (c) a clustering guaranteeing deadlines obtained after modifying message periods appropriately.

Fig. 7 shows the synthesis algorithm to construct the network topology. For each  $p_{\text{base}}$  value between  $[p_{\min}/2, p_{\min}]$ , message periods are modified appropriately, and clustered to generate the corresponding topology. Finally, the best solution, in terms of the number of clusters, is chosen.

The CLUSTER procedure in Fig. 8 takes a set of messages  $s_{msg}$  as input, their periods modified and sorted in terms of increasing period $(m_i)$ , and returns the set of message clusters  $s_{clust}$  as output. During each clustering step, we choose a *k*-FT message  $m_i$  having the minimum period within  $s_{msg}$  and allocate it to *k* separate clusters.

For each  $m_i$ , we obtain all feasible message-to-cluster allocations by grouping  $m_i$  with each  $C_j$  in  $s_{clust}$  and generating round $(C_j \cup m_i)$ . If needed, new clusters are created within  $s_{clust}$  to accommodate all copies of  $m_i$ . If more than k feasible allocations are obtained, then the k best solutions are chosen based on efficient bandwidth use. The exact evaluation criterion is discussed later in this section.

The ALLOC procedure generates a feasible round  $(C_j \cup m_i)$ . It accepts an existing message cluster  $C_j$  and a message  $m_i$  and generates a feasible TDMA round (if possible) for the new allocation  $C_j \cup m_i$ . As discussed above, message  $m_i$ 's period, period $(m_i)$  is first transformed to relate

```
Procedure SYNTH (\{m_i\})
                                             /* \{m_i\} := Message set */
p_{\min} = \min\{period(m_i)\};
                                            /* p_{\min} denotes the minimum period in the message set */
cost_{min} := Number of messages in \{m_i\}; /* Topology cost where each m_i is allotted a dedicated bus */
s_{msg} := \emptyset;
                                        /* Initialize the message set */
for (each p_{\text{base}} in \left[\frac{p_{\min}}{2}, p_{\min}\right]) begin
    s_{\text{msg}} := \{m_i \mid m_i \text{'s period is the largest integer such that } 2^k \cdot p_{\text{base}} \le delay(m_i) < 2^{k+1} \cdot p_{\text{base}}\};
    Sort messages in s_{msg} by increasing period;
    s_{clust} := CLUSTER(s_{msg});
                                            /* s<sub>clust</sub>:= set of clusters */
    cost_{cur} := Number of clusters in s<sub>clust</sub>;
    if (cost_{cur} < cost_{min}) begin
         cost_{min} := cost_{cur};
         Store sclust as current best solution;
    end:
     s_{msg} := \emptyset;
end:
return s<sub>clust</sub>;
                      /* Return the best allocation */
```

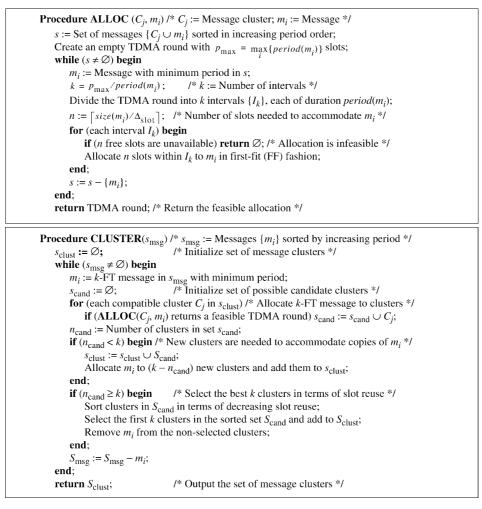

Fig. 8. The clustering algorithm generating the reduced-cost network topology.

harmonically to those in  $C_j$  and the messages are sorted in increasing period order. The duration of the new round, round $(C_j \cup m_i)$  is  $p_{\max} = \max_{C_j} \{\text{period}(m_i)\}$ . To allocate transmission slots for the new message  $m_i$ , ALLOC divides round $(C_j)$  into k disjoint time intervals  $\{I_k\}$  where  $k = p_{\max}/period(m_i)$  and  $I_k$  has duration period $(m_i)$ . Transmission slots are then allotted within each interval using the FF packing strategy. The distance constraint between transmission slots for  $m_i$  is guaranteed since the allotted slots occur in the same positions within each interval  $I_k$ .

The computational complexity of the synthesis procedure is  $O(n^3)$  where *n* is the number of messages; the outer while loop of CLUSTER iterates through all *n* messages, and during each iteration, ALLOC explores all message to cluster allocations, a process of complexity  $O(n^2)$ .

**Theorem 1.** Given a cluster  $C_j = \{m_1, ..., m_n\}$  with harmonically related message periods, the TDMA round generated by ALLOC guarantees message transmission deadlines.

**Proof.** We show by induction on the number of messages that for each  $m_i$  in  $C_j$ , and during any time interval corresponding to period( $m_i$ ), ALLOC allocates a sufficient

number of transmission slots to send  $m_i$ . Assume that the messages  $\{m_1, ..., m_n\}$  are ordered in terms of increasing period. Also, let  $I_k^{m_i}$  be the *k*th interval within the TDMA round containing transmission slots for message  $m_i$ .

Consider the base case when allocating the first message  $m_1$  within the TDMA round of duration  $p_{\text{max}}$ . The round is divided into intervals  $\{I_k^{m_1}\}$ , each of duration period $(m_1)$ . Initially, all slots within the round are free and the FF packing scheme allots the first available slots within each interval to  $m_1$ . The maximum distance between two successive  $m_1$  transmission slots equals period $(m_1)$ , and thus, ALLOC guarantees  $m_1$ 's deadline.

Now, assume that transmission slots have been previously allotted for messages  $\{m_1, ..., m_i\}$  to satisfy their respective distance constraints, and let  $m_{i+1}$  be the next message being considered. As before, the round is divided into intervals  $\{I_k^{m_{i+1}}\}$ . Since messages are ordered in terms of increasing period,  $I_k^{m_{i+1}} = pI_k^{m_i}$ ,  $p \ge 1$ . We consider the following cases:

p=1. Both intervals have the same duration. Since the allocated slots for  $m_i$  satisfy its minimum distance constraint, all allotted and free slots occur in the same

positions within  $I_k^{m_1}$ . The FF scheme chooses the first available slots within each  $I_k^{m_1}$  to accommodate  $m_{i+1}$ . Therefore, the newly allotted slots for  $m_{i+1}$  also occur in the same positions within each interval.

p > 1. Since message periods are harmonic multiples of each other, each  $I_k^{m_{i+1}}$  spans the same number of  $m_i$  intervals. Furthermore, since each  $m_i$  interval is identical in terms of the slot occurrences, it follows that each  $I_k^{m_{i+1}}$ , comprising a sequence of these intervals, is also identical. Therefore, the FF scheme chooses slots occurring in the same positions within  $I_k^{m_{i+1}}$  for message  $m_{i+1}$ .

**Theorem 2.** Given a cluster  $C_j = \{m_1, ..., m_n\}$  where the message periods are harmonically related, ALLOC guarantees a feasible message allocation if one exists.

**Proof**. We prove this theorem by showing that if ALLOC fails to find a feasible allocation for  $C_i$ , then no other packing scheme will. Given a feasible TDMA round for messages  $\{m_1, \dots, m_i\}$ , ALLOC fails to find an allocation for the new message  $m_{i+1}$  only if the number of transmission slots within an interval  $I_k^{m_{i+1}}$  is insufficient. Clearly, rearranging messages within this interval does not increase the number of available slots. Now assume  $m_{i+1}$  is successfully allocated within  $I_k^{m_{i+1}}$  after removing a previously allocated message  $m_i$ . This implies that  $m_{i+1}$ now occupies some slots previously used by  $m_i$ . However, since  $I_k^{m_i} \leq I_k^{m_{i+1}}$ , there exists at least one interval where  $m_i$ cannot be accommodated (All slots in the interval are allocated). Therefore, no feasible allocation for the cluster  $C_i$  exists. 

# 4.1. Transmission-slot reuse

Recall that during clustering, each message  $m_i$  is treated as periodic with period, period $(m_i)$ . However, if the task  $T_i$ transmitting  $m_i$  does not execute at that rate, then the bus bandwidth is over-utilized. We can improve bandwidth utilization by reusing transmission slots among the multiple messages sent by processor  $P_i$ .

The worst-case arrival rate arrival( $m_i$ ) for each message  $m_i$  in a multi-rate system is obtained during schedulability analysis by simulating the corresponding task schedule. It is important to note that arrival( $m_i$ ), expressed in terms of slot intervals, depends on the execution rate of the sender task  $T_i$ . Let  $\{m_i\}$  be the set of messages sent by a processor within a message cluster  $C_j$ . Now, assume message  $m_{\text{new}}$ , also transmitted by the same processor, to be allotted slots within round( $C_j$ ). If each message  $m_i$  is allotted  $n_i$  transmission slots within the time interval period( $m_{\text{new}}$ ) in round( $C_j$ ), then the number of slots available for reuse by  $m_{\text{new}}$  is

$$n_{\text{reuse}} = \sum_{m_i} n_i - \sum_{m_i} \left[ \frac{\text{period}(m_{\text{new}})}{\operatorname{arrival}(m_i)} \right] n_i$$

where  $arrival(m_i)$  denotes the worst-case arrival rate of message  $m_i$ . Therefore,  $m_{new}$  is allotted

$$\frac{\text{size}(m_{\text{new}})}{B_j^{\text{speed}} \Delta_{\text{slot}}} - n_{\text{reuse}}$$

transmission slots within period( $m_{\text{new}}$ ).

Fig. 9 shows an example of slot reuse among four messages sent by a processor assuming a network bandwidth of 250 KB/s and slot width of 50  $\mu$ s. Fig. 9(a) lists message attributes in increasing order of their periods

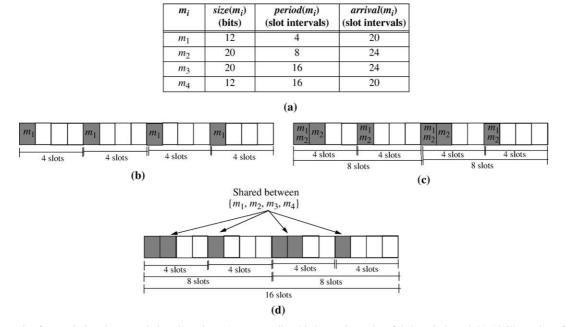

Fig. 9. An example of transmission slot reuse during allocation: (a) messages listed in increasing order of their periods, and (b)–(d) illustration of slot reuse as messages are added to the TDMA round.

and Fig. 9(b)–(d) show how slots are reused between messages while constructing the TDMA round. In Fig. 9(b),  $m_1$  is allotted one transmission slot during any time interval spanning period( $m_1$ ). Before allotting slots for  $m_2$ , the number of reusable slots during period( $m_2$ ) is determined as 2-[8/20]1=1;  $m_1$  may use one transmission slot during any period( $m_2$ ). Since  $m_2$  requires two slots for transmission, we allot one additional slot per period( $m_2$ ) in Fig. 9(c). When allocating  $m_3$ , we determine the number of reusable slots within period( $m_3$ ) as 6-([16/20]1+[16/24]2)=3. Since,  $m_3$ may reuse three slots during any period( $m_3$ ), no new slots are allotted. A similar argument holds when allocating message  $m_4$ . It is straightforward to extend the ALLOC procedure to include slot reuse.

# **Theorem 3**. The TDMA round generated by ALLOC for the cluster $C_j$ with transmission-slot reuse guarantees message deadlines.

**Proof.** We show by induction on the number of messages that for each message  $m_i$  sent by processor  $P_j$ , ALLOC allocates a sufficient number of sending slots during any period( $m_i$ ) even when its slots are reused by other messages.

As before, we assume that messages are ordered in terms of increasing period.

Consider the base case where the first message  $m_1$  is allotted to an empty TDMA round. No slots can be reused and  $m_1$  is simply allotted enough transmission slots during any period $(m_1)$  span. Now, assume messages  $\{m_1,...,m_i\}$ sent by  $P_j$  have been allotted slots satisfying their deadlines and a new message  $m_{new}$ , also sent by  $P_j$ , needs to be grouped with this set. In the worst case, during any time interval spanning period $(m_{new})$ , the previously scheduled messages may use up to

$$\sum_{m_i} \left[ \frac{\text{period}(m_{\text{new}})}{\text{arrival}(m_i)} \right] n_i$$

slots for transmission. Since  $m_{\text{new}}$  is sent only during the unused slots (see above discussion), messages  $\{m_1, \dots, m_i\}$  continue to meet deadlines even when some of their transmission slots are reused.

Given a set of clusters and a new message to be allocated to one, CLUSTER explores all possible cluster-message

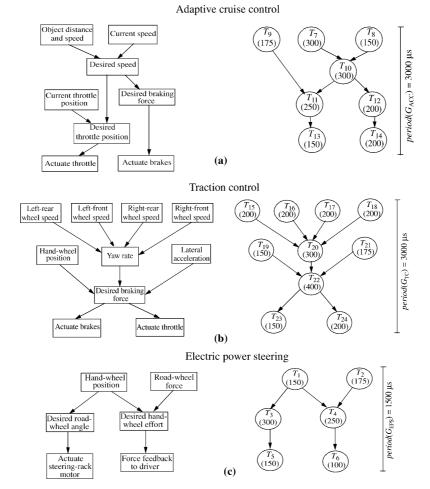

Fig. 10. (a) Adaptive cruise control, (b) traction control, and (c) electric power steering applications, and the corresponding flow-graph representations.

allocation scenarios. Slot reuse is used as the deciding factor in selecting the best allocation since the cluster allocation resulting in maximum reuse minimizes the bandwidth utilization. Finally, when TDMA slots are shared between messages sent by a processor, as in Fig. 9(d), the communication co-processor must correctly schedule their transmission, i.e. given a slot, decide which message to transmit in it. Though this paper does not address messagescheduling logic within the co-processor, an earliest-deadline first approach seems appropriate.

# 5. Case study

We now illustrate the proposed synthesis method using some advanced automotive control applications as examples. These include adaptive cruise control (ACC), electric power steering (EPS), and traction control (TC), and are detailed in Fig. 10(a)-(c). The ACC application automatically maintains a safe following distance between two cars, while EPS uses an electric motor to provide necessary steering assistance to the driver. The TC application actively stabilizes the vehicle to maintain its intended path even under slippery road conditions. These applications demand timely interaction between distributed sensors, processors, and actuators, i.e. have specific end-toend deadlines, and therefore require a dependable communication network. Fig. 11(a) shows the physical architecture of the system where sensors and actuators are directly connected to the network and the designer-specified task-to-processor allocation, while Fig. 11(b) summarizes the various message attributes affecting network topology generation. We assume 1-FT messages throughout. Columns two and three list the sending and receiving tasks for

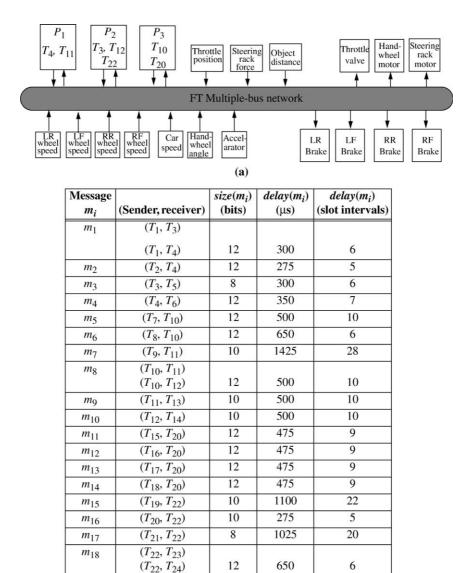

Fig. 11. (a) The physical architecture including task-to-processor allocation and (b) the message attributes required for network topology construction.

(b)

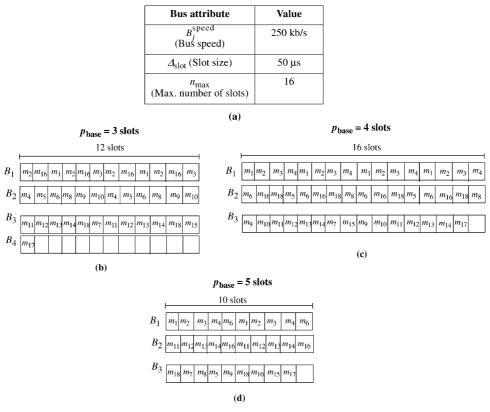

Fig. 12. (a) Example TDMA round specifications and (b) communication schedules generated without slot reuse where message periods are modified to relate harmonically to (b)  $p_{\text{base}}=3$ , (c)  $p_{\text{base}}=4$ , and (d)  $p_{\text{base}}=5$  slots, respectively.

each message and the message size  $size(m_i)$  in bits, respectively, while columns four and five list the communication delay,  $delay(m_i)$  for messages in microseconds, and transmission-slot intervals. These delay values are obtained by first assigning deadlines to tasks and then performing a schedulability analysis on their respective processors (see Section 3).

As summarized in Fig. 12(a), we assume a version of the FlexRay communication protocol having a bandwidth of 250 KB/s and a minimum transmission-slot width of 50  $\mu$ s. Since  $m_2$  and  $m_{16}$  have the minimum period of five slots among all messages,  $p_{\text{base}}$  may assume values of three, four, or five slots. Fig. 12(a)–(c) show the communication schedules generated by SYNTH (without slot reuse) after modifying the message periods to relate harmonically to each of the above  $p_{\text{base}}$  values. Those corresponding to  $p_{\text{base}}$  values of 4 and 5 slots compare best in terms of topology cost.

We now show how to reduce bandwidth utilization by sharing transmission slots between messages. As candidates for slot reuse, consider messages  $m_3$  and  $m_{10}$  sent by tasks  $T_3$ and  $T_{12}$ , respectively, where both tasks are allocated to processor  $P_2$ . In Fig. 13(a), where message periods are modified using  $p_{\text{base}}=3$ ,  $m_3$  and  $m_{10}$  cannot share slots since both have a periodicity of six slots. In Fig. 13(b), however, when their periods are modified as period( $m_3$ )=4 and period( $m_{10}$ )=8 using  $p_{\text{base}}=4$  slots, reuse is possible. Note that the EPS application comprising  $T_3$  transmitting  $m_3$  has a 1500 µs period-corresponding to the inter-interval time between successive  $m_3$  transmissions. Therefore, in Fig. 12(b),  $m_3$  requires only one of four allocated slots on bus  $B_1$  (Task  $T_3$ , however, may request  $m_3$ 's transmission anytime during the round), and  $m_{10}$  with a period of eight slots can reuse the one free slot available during any period( $m_{10}$ ). A similar argument holds for messages  $m_4$  and  $m_9$  sent by processor  $P_1$ . Fig. 12(c) shows the schedule corresponding to  $p_{\text{base}}=5$  slots. Again, slots are reused between messages { $m_3, m_{10}$ } and { $m_4, m_9$ }.

Finally, though the topologies in Fig. 13(b) and (c) have the same cost (three buses each), Fig. 13(b) has a somewhat lower slot utilization of 89.5% compared to 90% for Fig. 13(c). Since the empty slots in Fig. 13(b) may be used to transmit additional (non-critical) messages when compared to Fig. 13(c), we select the topology in Fig. 13(b) as the final solution.

# 6. Conclusions

This paper has addressed the synthesis of low-cost TDMA communication networks for distributed embedded systems. We have developed a fault-tolerant clustering method which allocates and schedules k-FT messages on the minimum number of buses to provide dependable transmission. The proposed method was illustrated using a case

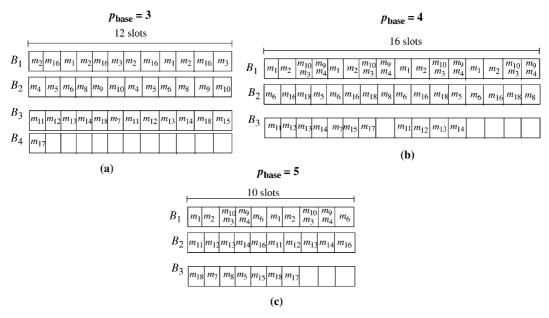

Fig. 13. Communication schedules generated while reusing transmission slots for different values of  $p_{\text{base}}$ : (a)  $p_{\text{base}}$ =3, (b)  $p_{\text{base}}$ =4, and (c)  $p_{\text{base}}$ =5 slots.

study involving some advanced automotive control applications and it was shown that sharing transmission slots among multiple messages reduces bandwidth consumption while preserving predictable communication. Therefore, the method has the potential to reduce topology cost when applied to larger embedded systems.

This paper does not address the design and implementation of the message scheduler on the co-processors (responsible for transmitting and receiving messages in their respective slots). We also do not address the fault-tolerant allocation of tasks to processors. The message clustering scheme can be easily incorporated into an overall synthesis scheme dealing with both task and message allocation. These issues will be investigated as part of future work.
